ABSTRACT

The use of alternative foundations for constructing more secure and efficient cryptographic schemes is a topic worth exploring. In the case of proxy re-encryption, the vast majority of schemes are based on number theoretic problems such as the discrete logarithm. In this paper we present NTRUReEncrypt, a new bidirectional and multihop proxy re-encryption scheme based on NTRU, a widely known lattice-based cryptosystem. We provide two versions of our scheme: the first one is based on the conventional NTRU encryption scheme and, although it lacks a security proof, remains as efficient as its predecessor; the second one is based on a variant of NTRU proposed by Stehlé and Steinfeld, which is proven CPA-secure under the hardness of the Ring-LWE problem. To the best of our knowledge, our proposals are the first proxy re-encryption schemes to be based on the NTRU primitive. In addition, we provide experimental results to show the efficiency of our proposal, as well as a comparison with previous proxy re-encryption schemes, which confirms that our first scheme outperforms the rest by an order of magnitude.

E.3 [Data Encryption]: Public Key Cryptosystems

1. INTRODUCTION

Proxy re-encryption is a type of public-key cryptographic scheme that enables a user to delegate her decryption rights to other users. From a high-level viewpoint, a proxy re-encryption scheme is an asymmetric encryption scheme that permits a proxy to transform ciphertexts under Alice’s public key $pk_A$ into ciphertexts decryptable by Bob’s secret key $sk_B$. In order to do this, the proxy is given a re-encryption key $r_{k_A \rightarrow k_B}$, which makes this process possible. So, besides defining traditional encryption and decryption functions, a proxy re-encryption scheme also defines a re-encryption function for executing the transformation.

Since the introduction of proxy re-encryption by Blaze et al. in 1998 [11], many proxy re-encryption schemes have been proposed. The vast majority of these schemes are based on bilinear pairings, which have several drawbacks. For instance, pairings are known to be computationally intensive operations. With respect to security, pairing-based proxy re-encryption schemes ultimately rely on the hardness of the discrete logarithm problem. This poses a problem in the case that efficient cryptanalytic attacks against the discrete logarithm problem are developed or quantum computation becomes practical. This problem is also applicable to other schemes not based on pairings but that also depend on the discrete logarithm or on integer factorization assumptions.

Apart from bilinear pairings, the use of other foundations for constructing proxy re-encryption schemes has received little attention. Recently, some lattice-based proxy re-encryption schemes have been proposed [29, 4]. Lattice-based cryptography is a promising field, chiefly because of its role in post-quantum cryptography, but in some particular cases, also for its efficiency. As a prime example of widely-accepted and efficient lattice-based cryptosystem we find NTRU, which was introduced in 1996 by Hoffstein, Pipher and Silverman [20]. Since then, it has remained as the most practical lattice-based public-key cryptosystem, at the point of being standardized by IEEE Std 1363.1-2008 [28] and ANSI X9.98-2010 [2]. One of the main reasons of NTRU’s popularity is its overwhelming performance with respect to traditional public-key cryptosystems. For instance, optimized versions of NTRU executed on a GPU proved to be up to 1000 times faster than RSA and 100 times faster than ECC [19]. The results behind the efficiency of NTRU are explained by the simplicity of its basic underlying operation, which is the convolution, i.e., the polynomial multiplication. NTRU uses polynomials with relatively small coefficients, so multiplications can be efficiently performed, even in constrained devices [8]. Another implication of this is that the size of the keys is relatively compact, when compared to other lattice-based schemes. In addition, the convolution operation can even be parallelized, which is very convenient as multicore and GPU processors are becoming more relevant nowadays.

One of the main drawbacks of NTRU is that it lacks a formal security proof, so its security stems from the practicality of best known attacks. This has meant that, over the
years, NTRU has followed a somewhat “break-and-repair” approach, where advances in attacks have stimulated changes in the scheme and its set of parameters, although it has remained essentially the same. In order to advance towards solving this gap, Stehlé and Steinfeld proposed in 2011 a provable-secure variant of NTRU [25, 26], whose security is based on the assumed hardness of lattice problems.

Our contribution. In this paper, we propose new bidirectional proxy re-encryption schemes based on NTRU. Our first result, NTRUReEncrypt, is a slight modification of the conventional NTRU encryption scheme; this proposal extends the original scheme in order to support re-encryption, thus it remains just as efficient. However, it lacks of a formal security proof, as does NTRU. For this reason, we also present PS-NTRUReEncrypt, a provably-secure variant based on the variant of the NTRU primitive proposed by Stehlé and Steinfeld in [25, 26]. To the best of our knowledge these are the first proxy re-encryption schemes based on NTRU, and of the first to be based on lattices. In addition, we complement our proposal with an experimental comparison of the performance of several proxy re-encryption schemes, which confirms that our first scheme outperforms the rest by an order of magnitude.

Related work. The notion of proxy re-encryption was introduced in 1998 by Blaze et al. [11]; their proposal, which is usually referred to as the BBS scheme, is bidirectional (it is trivial to obtain rk_{B→A} from rk_{A→B}) and multihop (the re-encryption process can be repeated multiple times), but not resistant to collisions between the proxy and one of the users. Ateniese, Fu, Green and Hohenberger proposed in [6] new proxy re-encryption schemes based on bilinear pairings. Their schemes are unidirectional, unihop and resistant to collisions. Green and Atienza propose an identity-based proxy re-encryption scheme in [18]; however, this scheme is not resistant to collisions. An improved proposal that is secure against chosen-ciphertext attacks (CCA) is presented in [13], but again, it is not collision-resistant. In [12], Canetti and Hohenberger present a CCA-secure bidirectional scheme; based on this security model, Libert and Vergnaud propose in [21] a unidirectional scheme with chosen-ciphertext security in the standard model. Another interesting proposal is presented in [5], where the authors define the notion of key privacy in the context of proxy re-encryption, which prevents the proxy to derive the identities of both sender and receiver from a re-encryption key.

As mentioned, the security in these schemes is based on number theoretic assumptions, such as the hardness of the discrete logarithm problem, but the use of other foundations for constructing proxy re-encryption schemes has been much less explored. In [29], Xagawa and Tanaka present the first lattice-based proxy re-encryption scheme, which relies on the Learning With Errors (LWE) problem; this scheme is bidirectional, multihop and CPA-secure. After this seminal work, Aono et al [4] proposed a unidirectional and multihop scheme, also based on the LWE problem.

With regard to the NTRU primitive, it has already been used as the basis for constructing other cryptographic schemes, such as multikey fully homomorphic encryption [22], private information retrieval [3], and public key traitor tracing scheme [23].

Organization. The rest of this paper is organized as follows: In Section 2, we provide some basic definitions for bidirectional proxy re-encryption schemes. In Section 3, we describe the NTRU encryption scheme and, based on it, we present our bidirectional proxy re-encryption scheme NTRUReEncrypt. In Section 4, we describe the provably-secure version of NTRU from Stehlé and Steinfeld and present our second scheme, PS-NTRUReEncrypt. In Section 5, we describe the experimental results from a prototype implementation of our proposals, as well as a comparison with previous proxy re-encryption schemes. Finally, Section 6 concludes the paper and future work is outlined.

2. DEFINITIONS

In this section, we provide some basic definitions relevant to bidirectional proxy re-encryption schemes. We first define the specification of a bidirectional CPA-secure proxy re-encryption scheme, based on the one given by Canetti and Hohenberger [12].

Definition 1. Bidirectional PRE. A bidirectional proxy re-encryption scheme is a tuple of algorithms (Setup, KeyGen, ReKeyGen, Enc, ReEnc, Dec):

- Setup(1^k) → params. On input the security parameter 1^k, the setup algorithm Setup outputs the parameters params.

- KeyGen() → (pk_A, sk_A). The key generation algorithm KeyGen outputs a pair of public and secret keys (pk_A, sk_A) for user A.

- ReKeyGen((sk_A, sk_B) → rk_{A→B}. On input the secret keys sk_A and sk_B, the re-encryption key generation algorithm ReKeyGen outputs a re-encryption key rk_{A→B}.

- Enc(pk_A, M) → C_A. On input the public key pk_A and a message M ∈ M, the encryption algorithm Enc outputs a ciphertext C_A ∈ C.

- ReEnc(rk_{A→B}, C_A) → C_B. On input a re-encryption key rk_{A→B} and a ciphertext C_A ∈ C, the re-encryption algorithm ReEnc outputs a second ciphertext C_B ∈ C.

- Dec(sk_A, C_A) → M. On input the secret key sk_A and a ciphertext C_A ∈ C, the decryption algorithm Dec outputs a message M ∈ M.

Once we have defined which are the inputs and outputs of a bidirectional proxy re-encryption scheme, we formulate the concept of correctness, also based on the one given by [12]. In this case, as these kinds of schemes are usually multihop, we refer to multihop correctness (i.e., ciphertexts that can be re-encrypted multiple times).

Definition 2. Multihop Correctness. A bidirectional PRE scheme (Setup, KeyGen, ReKeyGen, Enc, ReEnc, Dec) is multihop correct with respect to plaintext space M if:

- For all (pk_A, sk_A) output by KeyGen and all messages M ∈ M, it holds that Dec(sk_A, Enc(pk_A, M)) = M.

- For any sequence of pairs (pk_i, sk_i) output by KeyGen, with 0 ≤ i ≤ N, all re-encryption keys rk_{i→i+1} output by ReKeyGen(sk_i, sk_{i+1}), with j < N, all messages

1In the following, we will assume params is globally known, so we will omit it in the functions.
3. A PROXY RE-ENCRYPTION SCHEME BASED ON NTRU

In this section we firstly introduce the conventional NTRU encryption scheme and describe its operation. Then, we extend it in order to construct a bidirectional multihop proxy re-encryption scheme.

3.1 The NTRU Encryption Scheme

The NTRU encryption scheme, originally proposed by Hoffstein, Pipher and Silverman in [20], is one of the first public key encryption schemes based on lattices. The main reason behind the interest in NTRU is its efficiency, which is much better than other public-key cryptosystems and is even comparable to symmetric ciphers. In addition, its security is conjectured to be based on hard problems over lattices, although it lacks a formal proof.

We now briefly describe the operation of NTRU. The original NTRU cryptosystem is defined over the quotient ring \( \mathbb{Z}[x]/(x^n - 1) \), where \( n \) is a prime parameter. Thus, elements of the ring \( \mathbb{R}_{\text{NTRU}} \) are integer polynomials of degree less than \( n \); the operators + and ∙ denote addition and multiplication in \( \mathbb{R}_{\text{NTRU}} \), respectively. Other parameters of NTRU are the integer \( q \), which is a small power of 2 of the same order of magnitude than \( n \), and the small polynomial \( p \in \mathbb{R}_{\text{NTRU}} \), which usually takes values \( p = 3 \) or \( p = x + 2 \). In general, operations over polynomials will be performed in \( \mathbb{R}_{\text{NTRU}}/q \) or \( \mathbb{R}_{\text{NTRU}}/p \), which will be denoted respectively as \( \mathbb{R}_{\text{NTRU}}/q \) and \( \mathbb{R}_{\text{NTRU}}/p \).

In NTRU, the private key \( sk \) consists of a polynomial \( f \in \mathbb{R}_{\text{NTRU}} \) chosen at random, with a determined number of coefficients equal to 0, -1, and 1. The polynomial \( f \) must have an inverse in \( \mathbb{R}_{\text{NTRU}}/q \) and \( \mathbb{R}_{\text{NTRU}}/p \), respectively, \( f^{-1}_q \) and \( f^{-1}_p \). For efficiency, \( f \) can be chosen to be congruent to 1 modulo \( p \). The public key \( pk \) consists of the polynomial \( h = p \cdot g \cdot f^{-1}_p \mod q \), where \( g \in \mathbb{R}_{\text{NTRU}} \) is chosen at random.

The encryption process is very simple: a plaintext \( M \) from message space \( \mathbb{R}_{\text{NTRU}}/p \) is encrypted to ciphertext \( C = h \cdot s + M \mod q \), where \( s \) is a small random polynomial in \( \mathbb{R}_{\text{NTRU}} \). For decrypting a ciphertext \( C \), one must first compute \( C' = f \cdot C \) and reduce it modulo \( q \). If the original polynomial \( C' \) is sufficiently small then the result of the reduction is \( p s + fM \in \mathbb{R}_{\text{NTRU}}/q \). Next, \( C' \) is reduced modulo \( p \), obtaining \( fM \). Finally, this result is multiplied by \( f^{-1}_p \) to extract the original message \( M \); note that the last step is redundant if \( f \) was selected congruent to 1 modulo \( p \).

3.2 NTRUReEncrypt

Based on the NTRU encryption scheme, we define the proxy re-encryption scheme NTRUReEncrypt. Our proposal is essentially an extension of the scheme that includes the definition of the re-encryption and re-encryption key generation algorithms. One of the fundamental differences of our scheme with respect to the original NTRU is that the secret polynomial \( f \) has to be congruent to 1 mod \( p \), not for efficiency reasons, but because it is necessary to correctly decrypt re-encrypted ciphertexts.

3.2.1 The scheme

Now we present our scheme NTRUReEncrypt. In the following, the delegator is represented by user \( A \), whereas the delegatee is user \( B \). Our scheme is specified by the following algorithms:
The inclusion of the random term \( c \) during the re-encryption phase is necessary in order to prevent a simple ciphertext-only attack from the delegatee. Imagine that a re-encrypted ciphertext is of the form \( C_B = C_A \cdot r_{kA \rightarrow B} = C_A \cdot f_A \cdot f_B^{-1} \); that is, without the random term \( c \). Then, the delegatee could extract the secret key of the delegator based on the observation that \( C_B \cdot f_B = C_A \cdot f_A \) holds, since \( C_B = C_A \cdot r_{kA \rightarrow B} \). Next, assuming that \( C_A \) is invertible modulo \( q \), the attacker can extract the secret key by computing \( f_A = C_A^{-1} \cdot C_B \cdot f_B \).

The scheme is also multihop, that is, it supports multiple re-encryptions. However, this property is limited, since the addition of the error term during the re-encryption produces an increasing error that grows on each hop, until eventually, decryption fails. Our experiments show that this depends heavily on the choice of parameters. This issue is discussed in more detail in Section 5.1.

### 3.2.3 Analysis

The resulting proxy re-encryption scheme preserves the performance level of the original NTRU; a detailed experiment on this matter is presented in Sections 5.1 and 5.2. These experimental results show that NTRUReEncrypt outperforms other proxy re-encryption schemes by an order of magnitude.

A theoretical analysis of the computational costs associated with NTRUReEncrypt shows that the main algorithms, namely encryption, decryption and re-encryption, only need a single multiplication (actually, re-encryption takes an additional multiplication for computing the term \( pe \), but this can be computed beforehand and, in addition, the polynomial \( p \) is small and known in advance). As already stated in the introduction, the core operation in NTRU is the multiplication of polynomials, which can be done in \( O(n \log n) \) time using the Fast Fourier Transform (FFT) [19].

</tbody>
</table>

As for the space costs associated to NTRUReEncrypt, Table 1 presents a theoretical analysis of the size of the messages, keys, and ciphertexts, as well as a measure of the ciphertext expansion it produces. It can be seen that the expansion is logarithmic in the parameter \( q \), and that the size of keys is within \( O(n \log_2 q) \). This can be put in contrast with other lattice-based cryptosystems, such as the proxy re-encryption scheme from Aono et al [4], where keys and messages are typically matrices whose dimensions grow linearly with the parameter \( n \). This implies that the size of these matrices is at least quadratic with respect to \( n \).

Table 2 illustrates this fact by showing a comparison between Aono’s scheme and ours. The space costs from Aono’s scheme are determined by the parameters shown in [4] for the case of 143 bits of security and 128-bit plaintexts, whereas our figures are calculated using a parameter set that achieves 256 bits of security and supports up to 186-bits plaintexts. More details about the parameters used are given in Section 5.1. It can be seen that our space costs are lower in
comparison, even considering the difference in bits of security. In the case of re-encryption keys, the difference in size is remarkable as it grows up to 3 orders of magnitude. On the other hand, our ciphertexts are slightly bigger. Another interesting fact is that we use the same kind of polynomials for conveying all the types of keys and ciphertexts, so the space costs are the same in all cases (1.57 KB).

It is easy to check that our scheme is bidirectional. Given \( r_{k_{A \rightarrow B}} = fAfB^{-1} \), the proxy can easily compute \( r_{k_{B \rightarrow A}} = (r_{k_{A \rightarrow B}})^{-1} = fbfA^{-1} \). This property is a consequence of how re-encryption keys are constructed (\( r_{k_{A \rightarrow B}} = sk_A \cdot sk_B^* \)), in the same way as in other bidirectional schemes [11, 12, 27].

With respect to the security of the scheme, we cannot overcome the problem of NTRU lacking a formal security proof. However, we can study it from a practical view, as NTRU does. For instance, the time required for a lattice-based attack to the public key is conjectured to be exponential in \( n \) [20]. This is also relevant to the re-encryption scheme since extracting private keys from the re-encryption key is at least as hard as attacking NTRU public key, as they are constructed in the same way: for instance, the public key of user \( B \) is of the form \( pqfB^{-1} \), whereas re-encryption key \( r_{k_{A \rightarrow B}} \) is of the form \( fAfB^{-1} \). In NTRU, the polynomials \( f \) are larger than the polynomials \( g \), i.e., they have more non-zero terms, so the term \( f_A \) of a re-encryption key would be larger than the term \( pg_B \) of a public key. However, as it happens to the majority of bidirectional proxy re-encryption schemes [11, 12, 27], our scheme is not collusion-safe. That is, it is vulnerable to a collusion of the proxy and the users, since extracting the delegator’s secret key \( f_A \) is as simple as computing \( r_{k_{A \rightarrow B}} \cdot f_B \). The same problem applies to the delegatee’s secret key.

As a way to provide a formal security proof of our scheme, we explored how this problem has been addressed in the literature. An interesting approach is made by Stehlé and Steinfeld in [25, 26], where they present a variant of NTRU which is proven CPA-secure under lattice-based assumptions. Based on this solution, we build a second version of our NTRU-based proxy re-encryption scheme, called PS-NTRUReEncrypt, which is provably-secure.

### 4. PROVABLY SECURE NTRU

In this section we provide a second proxy re-encryption scheme, called PS-NTRUReEncrypt, that is provably secure under a hard problem for lattices, namely the Ring-LWE assumption. Before explaining our provably-secure scheme, we must first establish some background concepts; after that, we describe the NTRU variant proposed in [25, 26] by Stehlé and Steinfeld, which serves as a basis for our second scheme.

#### 4.1 Background

Before continuing, we provide some basic definitions and present the notation that is used throughout this section. Most of these definitions and notation is taken from [25, 26].

Let \( \Phi(x) = x^n + 1 \), with \( n \) a power of 2; that is, \( \Phi(x) \) is the 2\( n \)-th cyclotomic polynomial. Let \( q \) be a prime integer such that \( q = 1 \mod 2n \). Let \( \mathcal{R} \) be the ring \( \mathbb{Z}[x]/\Phi(x) \), and \( \mathcal{R}_Q = \mathcal{R}/q = \mathbb{Z}_q[x]/\Phi(x) \). We will denote the set of invertible elements of \( \mathcal{R}_Q \) as \( \mathcal{R}_Q^\times \). Although elements of \( \mathcal{R} \) are polynomials, we often treat them as vectors. We denote by \( \| \cdot \| \) and \( \| \cdot \|_\infty \) the Euclidean norm and infinite norm, respectively. During the proofs in Section 4.3.1 and 4.3.2, we use the asymptotic notations \( O(\cdot) \), \( o(\cdot) \), \( \Omega(\cdot) \). A function \( f(n) \) is negligible if \( f(n) = n^{-\omega(1)} \).

The Ring Learning With Errors (Ring-LWE) problem is a hard decisional problem based on lattices introduced by Lyubashevsky et al in [24]. In this paper, we use an adapted version of this problem found in [25, 26].

**Definition 4.** The Ring-LWE problem. Let \( s \in \mathcal{R}_Q \) and \( \psi \) a distribution over \( \mathcal{R}_Q^\times \), then we define \( A_{s,\psi} \) as the distribution that samples pairs of the form \((a, b), \) where \( a \) is chosen uniformly from \( \mathcal{R}_Q^\times \) and \( b = a \cdot s + e \), for some \( e \) sampled from \( \psi \). The distribution \( A_{s,\psi} \) is also called the Ring-LWE distribution. The Ring-LWE problem is to distinguish distribution \( A_{s,\psi} \) from a uniform distribution over \( \mathcal{R}_Q^\times \times \mathcal{R}_Q \). The Ring-LWE assumption is that this problem is computationally infeasible.

This variant of the Ring Learning With Errors problem is denoted in [25, 26] as the \( \text{R-LWE}_{\mathcal{R}_Q^\times} \) problem; however, we will not use that notation for simplicity. As in [25, 26], the error distributions \( \psi \) are sampled from a family of distributions \( \Psi_a \), with parameter \( a \); for more details of the definition of these distributions, see [25, 26].

#### 4.2 Provably Secure NTRU

Stehlé and Steinfeld proposed in [25, 26] a variant of the NTRU primitive which is proven CPA-secure under the hardness assumption of the Ring-LWE problem. This scheme is defined over the rings \( \mathcal{R} \) and \( \mathcal{R}_Q \), determined by parameters \( n \) and \( q \), as defined in previous section. The plaintext space \( \mathcal{M} \) corresponds to the ring \( \mathcal{R}/p \), where \( p \in \mathcal{R}_Q^\times \) is also a parameter of the scheme; as conventional NTRU, typical values for this parameter are \( p = 3 \) and \( p = x + 2 \), but in this scheme one may choose \( p = 2 \), since \( q \) is prime. The parameter \( \alpha \) characterizes the family of distributions \( \Psi_a \), and the parameter \( \sigma \) is the standard deviation of the Gaussian distribution used during the key generation algorithm. Thus, global parameters are a tuple \((n, q, p, \alpha, \sigma)\). The algorithms of this encryption scheme are the following:

- **KeyGen(\( A \))**: The output of the key generation algorithm for user \( A \) is the pair of public and secret keys \((pk_A, sk_A) \in \mathcal{R}_Q^\times \times \mathcal{R}_Q^\times \). Let \( \mathcal{D}_{2^n,\sigma} \) be the Gaussian distribution over \( \mathbb{Z}^n \) with standard deviation \( \sigma \). The keys are computed as follows:
  1. Sample \( f' \) from \( \mathcal{D}_{2^n,\sigma} \); let \( f_A = 1 + p \cdot f' \); if \( (f_A \mod q) \notin \mathcal{R}_Q^\times \), resample.
  2. Sample \( g_A \) from \( \mathcal{D}_{2^n,\sigma} \); if \( (g_A \mod q) \notin \mathcal{R}_Q^\times \), resample.
  3. Compute \( h_A = p \cdot g_A \cdot f_A^{-1} \).
  4. Return secret key \( sk_A = f_A \) and \( pk_A = h_A \).
- **Enc(\( pk_A, M \))**: On input the public key \( pk_A \) and a message \( M \in \mathcal{M} \), sample noise polynomials \( s, e \) from a
distribution from $\Psi_a$, and output ciphertext $C_A = h_A s + pe + M \in \mathcal{R}_q$.

- $\text{Dec}(sk_A, C_A)$. On input the secret key $sk_A = f_A$ and a ciphertext $C_A$, the decryption algorithm $\text{Dec}$ computes $C_A' = C_A \cdot f_A$ and outputs the message $M = (C_A' \mod p) \in \mathcal{M}$.

It can be seen that the operation of this scheme is very similar to the original NTRU, except for the generation of the keys and the inclusion of a noise term during encryptions. The authors prove that this NTRU variant is CPA-secure, over the hardness of the Ring-LWE problem. They also prove the correctness of their proposal, by establishing the conditions for avoiding decryption failures. Both proofs will serve as a basis for ours.

4.3 Provably-Secure NTRUReEncrypt

In this section we present the scheme PS-NTRUReEncrypt, which is based on the provably-secure variant of NTRU described in the previous section. This scheme uses the same global parameters as before, a tuple $(a, q, p, \alpha, \sigma)$. This scheme is defined by the following algorithms:

- $\text{KeyGen}()$: The output of the key generation algorithm for user $A$ is the pair of public and secret keys $(pk_A, sk_A) \in \mathcal{R}_q^* \times \mathcal{R}_q^*$. The keys are computed as follows:
  1. Sample $f' \in D_{2n, \sigma}$; let $f_A = 1 + p \cdot f'$; if $(f_A \mod q) \notin \mathcal{R}_q^*$, re-sample.
  2. Sample $g_A \in D_{2n, \sigma}$; if $(g_A \mod q) \notin \mathcal{R}_q^*$, re-sample.
  3. Compute $h_A = p \cdot g_A \cdot f_A^{-1}$.
  4. Return secret key $sk_A = f_A$ and $pk_A = h_A$.

- $\text{ReKeyGen}(sk_A, sk_B)$: On input the secret keys $sk_A = f_A$ and $sk_B = f_B$, the re-encryption key generation algorithm $\text{ReKeyGen}$ computes the re-encryption key between users $A$ and $B$ as $rk_{A \rightarrow B} = sk_A \cdot sk_B^{-1} = f_A \cdot f_B^{-1}$.

- $\text{Enc}(pk_A, M)$: On input the public key $pk_A$ and a message $M \in \mathcal{M}$, the encryption algorithm $\text{Enc}$ samples noise polynomials $s, e$ from a distribution from $\Psi_a$, and outputs ciphertext $C_A = h_A s + pe + M \in \mathcal{R}_q$.

- $\text{ReEnc}(rk_{A \rightarrow B}, C_A)$: On input a re-encryption key $rk_{A \rightarrow B}$ and a ciphertext $C_A$, the re-encryption algorithm $\text{ReEnc}$ samples noise polynomial $e'$ from a distribution from $\Psi_a$ and outputs ciphertext $C_B = C_A \cdot rk_{A \rightarrow B} + pe' \in \mathcal{R}_q$.

- $\text{Dec}(sk_A, C_A)$. On input the secret key $sk_A = f_A$ and a ciphertext $C_A$, the decryption algorithm $\text{Dec}$ computes $C_A' = C_A \cdot f_A$ and outputs the message $M = (C_A' \mod p) \in \mathcal{M}$.

It can be seen that this scheme is an extension of the one from Stehlé and Steinfeld, by including the definition of the re-encryption and re-encryption key generation algorithms. Note also that the same three-party protocol for computing the re-encryption key described in Section 3.2 for NTRUReEncrypt can be applied here.

4.3.1 Correctness

Following the description of the encryption, decryption and re-encryption algorithms, it is easy to informally check that the correctness conditions defined in Def. 2 are fulfilled:

- For all $(pk_A, sk_A)$ output by KeyGen and all messages $M \in \mathcal{M}$, it holds that $\text{Dec}(sk_A, \text{Enc}(pk_A, M)) = M$.

The evaluation of the encryption of an arbitrary message $M \in \mathcal{M}$ gives $\text{Dec}(\text{Enc}(M), \text{Dec}(\text{Enc}(M), \ldots)) = M$.

For any sequence of pairs $(pk_i, sk_i)$ output by KeyGen, with $0 \leq i \leq N$, all re-encryption keys $rk_{i \rightarrow i+1}$ output by $\text{ReKeyGen}(sk_j, sk_{j+1})$, with $j < N$, all messages $M \in \mathcal{M}$, and all ciphertexts $C_1$ output by $\text{Enc}(pk_1, M)$, it holds that:

$$\text{Dec}(sk_N, \text{ReEnc}(rk_{N-1 \rightarrow N}, \ldots \text{ReEnc}(rk_{1 \rightarrow 2}, C_1))) = M$$

If for any $M \in \mathcal{M}$ correctness holds only with probability $1$ minus a negligible quantity, we say that the scheme is correct with respect to $\mathcal{M}$.

Let us assume the sequence of secret keys $f_0, f_1, \ldots, f_N$. Since our scheme is multi-hop, a ciphertext re-encrypted $N$ times will be of the form:

$$C_N = pg_0 f_N^{-1} s + pe_0 f_N^{-1} + pe_1 f_1 f_N^{-1} + \ldots + pe_{N-1} f_N^{-1} + pe_N + M f_0 f_N^{-1}$$

$$= pg_0 f_N^{-1} s + \left[ \sum_{i=0}^{N-1} pe_i f_i f_N^{-1} \right] + pe_N + M f_0 f_N^{-1} \quad (1)$$

where $e_i$ denotes the additional error terms added during the re-encryptions, and $e_0$ is the error term from the first (and unique) encryption. When decrypting $C_N$, and assuming there are no decryption failures, one obtains:

$$C_N = C_N \cdot f_N = pg_0 s + \left[ \sum_{i=0}^{N} pe_i f_i \right] + M f_0 \quad (2)$$

Since, $f_0 = 1 \mod p$ and $pg_0 s = pe_1 f_1 = 0 \mod p$, for $0 \leq i \leq N$, then we have that $C_N \mod p = M$.

In the informal proof above, we have not considered the possibility of decryption failures. This is a recurring issue from the first definition of the NTRU cryptosystem. It can be seen that the re-encryption process produces an increase in the error terms of the ciphertexts, which can potentially lead to decryption failures. We will now describe the correctness conditions of NTRUReEncrypt and prove that the decryption algorithm is capable of handling this increase.

This proof is basically a slight extension of the one given in [26, Lemma 3.7] and generalizes single encryption as well as multiple re-encryptions; in this case, single encryption is handled as a particular case of multihop re-encryption (taking the number of re-encryptions $N = 0$).
Theorem 1. If $\text{deg}(p) \leq 1$, $\omega(n^{0.25} \log n)\alpha N\|p\|^2\sigma \leq 1$, and $n^{0.75} \leq \alpha q$, then the decryption algorithm of PS-NTRUReEncrypt succeeds in recovering $M$ with probability $1 - n^{-\omega(1)}$ over the choice of $s, e_i, f_i, g_i$, for $0 \leq i \leq N$.

Proof. As stated, a ciphertext $C_N$ re-encrypted $N$ times has the form described in Equation 1. When decrypting $C_N$, the decryption algorithm computes $C_N'''$, as described in Equation 2. This computation is implicitly performed modulo $q$, so $C_N''' \in \mathbb{R}_q$. However, let us define $C_N'' \in \mathbb{R}$, that is, not modulo $q$:

$$C_N'' = pg_0s + \sum_{i=0}^{N} p e_i f_i + M f_0 \in \mathbb{R}$$

In order for the decryption algorithm to succeed $\|C_N''\|_\infty \leq q/2$, so $C_N'' = C_N$ in $\mathbb{R}$. Since $f_0 = 1 \mod p$ and $pg_0s + pe_if_i = 0 \mod p$, for $0 \leq i \leq N$, then we have that $C_N'' \mod p = C_N \mod p = M$ and the decryption algorithm succeeds. Then, it is sufficient to give an upper bound on the probability that $\|C_N''\|_\infty \geq q/2$.

From Lemma 1 (see Appendix A), polynomials $g_0$ and $f_i$, for $0 \leq i \leq N$, have Euclidean norms $\leq 4\sqrt{\alpha}\|p\|\sigma$, with probability $\geq 1 - 2^{-n+3}$. From the properties of the ring $\mathbb{R}$, we know that for all $u, v \in \mathbb{R}$, $\|u + v\| \leq \sqrt{\|u\|^2 + \|v\|^2}$. As a particular case, since $\text{deg}(p) \leq 1$, then $\|p - u\| \leq 2\|p\|\cdot \|u\|$. Hence, it follows that $\|pg_0s\|, \|pg_0s\| \leq 8\sqrt{\alpha}n^{0.25}\|p\|\sigma$, with probability $\geq 1 - 2^{-n+3}$. Now, from Equation 2 (see Appendix A), if $n^{0.25} \leq \alpha q$ we have that with probability $\geq 1 - n^{-\omega(1)}$:

$$\|pg_0s\|, \|pg_0s\| \leq 8\alpha q n^{0.25} \omega(\log n)\|p\|^2\sigma$$

Apart from this, since $\|M\| \leq \|p\|$ [26], we know that:

$$\|f_0 M\| \leq \|f_0 M\| \leq 4n\|p\|^2\sigma$$

Hence $\|C_N''\|_\infty \leq \left(8(N+2)\alpha q n^{0.25} \omega(\log n) + 4n\right)\|p\|^2\sigma$, and taking $n^{0.75} \leq \alpha q$, then:

$$\|C_N''\|_\infty \leq \left(8(N+20)\alpha q n^{0.25} \omega(\log n)\|p\|^2\sigma$$

As we assumed initially that $\omega(n^{0.25} \log n)\alpha N\|p\|^2\sigma \leq 1$, then we have that $\|C_N''\|_\infty \leq q/2$, with probability $\geq 1 - n^{-\omega(1)}$.

It can be seen that for the case of single encryption ($N = 0$), the determined bounds are the same than in [26, Lemma 3.7].

4.3.2 Security proof

In this section, we proceed to prove that the scheme PS-NTRUReEncrypt is CPA-secure. This proof is also based on the one given in [26, Lemma 3.8].

Theorem 2. Suppose that $n$ is a power of 2, and $q$ a prime number such that $q = 1 \mod 2n$. Let $e \in (0, \frac{1}{2}, \delta) > 0, p \in \mathbb{R}_q^\ast$ and $\sigma \geq n\sqrt{\ln(8Mq^2)} \cdot q^{\delta + 1}$. If there exists and IND-CPA attack against PS-NTRUReEncrypt with probability $\frac{1}{2} + \delta$, then there exists an algorithm that solves the Ring-LWE problem with probability $\frac{1}{2} - q^{-\Omega(n)}$.

Proof. Let us assume, by contradiction, that we have an adversary $A$ that breaks PS-NTRUReEncrypt with probability $\frac{1}{2} + \delta$. We construct an algorithm $B$ against the Ring-LWE problem as follows:

Let $\mathcal{O}_\text{sample}$ be an oracle that samples tuples $(h', C')$ from either the uniform distribution over $\mathbb{R}_q^\ast \times \mathbb{R}_q$ or $A_\ast^\ast \times \mathbb{R}_q$. Algorithm $B$ first gets a sample $(h', C')$ from $\mathcal{O}_\text{sample}$. Next, $B$ generates target public key $pk^* = h' = p \cdot h'$ and gives $pk^*$ to $A$. Note that, regardless of the input distribution, $h'$ will be sampled uniformly from $\mathbb{R}_q^\ast$, and since $p \in \mathbb{R}_q^\ast$, then $h' = p \cdot h'$ is uniformly random in $\mathbb{R}_q^\ast$: however, by [26, Theorem 3], $h'$ is within negligible statistical distance $q^{-\Omega(n)}$ to public keys generated by KeyGen. $B$ will also generate an invalid, but correctly distributed, secret key polynomial $f^*$ as described in the first step of the key generation process, so target secret key is $sk^* = f^*$. Both honest and corrupted key generation are done as in the PS-NTRUReEncrypt scheme. Re-encryption key generation queries are done using the secret keys derived on the key generation queries. Once $A$ queries the challenge oracle with inputs $M_0$ and $M_1$, $B$ randomly picks $b \leftarrow \{0, 1\}$, and constructs the challenge ciphertext $C^* = p \cdot C^* + M_b$. Adversary $A$ receives $C^*$ and, eventually, outputs its guess $b'$; if $b = b'$, then algorithm $B$ outputs 1.

On the one hand, when the input to $B$ is a sample from $A_\ast^\ast \times \psi\ast$ then it will be of the form $(h', C' = h's + e)$, for some $s, e \leftarrow \psi$. In this case, the challenge ciphertext $C^*$ is a correct encryption of $M_b$ under $h^*$, since $C^* = p \cdot C^* + M_b = (p(h's + e)) + M_b = h's + pe + M_b$, and $A$ will succeed in distinguishing $M_b$ with probability $\frac{1}{2} + \delta - q^{-\Omega(n)}$. Hence, $B$ will determine that the sample was from the $A_\ast^\ast$, distribution with the same probability.

On the other hand, when the sample is from the uniform distribution over $\mathbb{R}_q^\ast \times \mathbb{R}_q$ then $C^*$ is uniformly random in $\mathbb{R}_q$, and since $p \in \mathbb{R}_q^\ast$, so is $p \cdot C^*$. The challenge ciphertext $C^* = p \cdot C^* + M_b$ will be then uniformly random in $\mathbb{R}_q$, as in the original distribution of ciphertexts, and independent of $b$. In this case, algorithm $B$ does not have any advantage in distinguishing the distribution and outputs 1 with probability $\frac{1}{2}$. Overall, algorithm $B$ succeeds with probability $(\frac{1}{2})(\frac{1}{2} + \delta - q^{-\Omega(n)}) + (\frac{1}{2})(\frac{1}{2}) = \frac{1}{2} + \frac{\delta}{2} - q^{-\Omega(n)}$. This contradicts the Ring-LWE assumption when $\delta$ is non-negligible.

Remark: In this simulation, each re-encryption key that involves the target public key is invalid, as generating a re-encryption key implies knowledge of the secret keys of the users involved. In this case, the target public key is constructed from $\mathcal{O}_\text{sample}$, so the simulator does not know the corresponding secret key. However, since the secret key of the target used generated at the beginning of the simulation is correctly distributed, any re-encryption key computed from this secret key is indistinguishable from a valid one. A similar argument is made in [18].

4.3.3 Analysis

The properties of PS-NTRUReEncrypt are the same as our first scheme. These properties are:

- Bidirectional: Given $rk_{A \rightarrow B} = f_A f_B^{-1}$, one can easily compute $rk_{B \rightarrow A} = (rk_{A \rightarrow B})^{-1} = f_B f_A^{-1}$.
- Multihop: It supports multiple re-encryptions, as shown in Section 4.3.1. Note that an error term is included during the re-encryption process, so the noise grows on each hop. Nevertheless, the correctness conditions presented before guarantee that the decryption
succeeds with overwhelming probability for proper parameters (which include the devised maximum number of hops, \( N \)). See also the results presented on Section 5.3.

- Not collusion-safe: This scheme suffers from the same vulnerability as NTRUReEncrypt, so secret keys can be extracted from the re-encryption key if the proxy colludes with a user involved. This problem is common in bidirectional proxy re-encryption schemes.

Table 3 shows the computational costs associated to PS-NTRUReEncrypt. As for our first scheme NTRUReEncrypt, the main operation here is the multiplication of polynomials, which is denoted by \( t_m \). In addition, another potentially costly operation is sampling from the noise distribution, denoted by \( t_s \). We distinguish here between on-line and off-line operations, as the latter can be performed beforehand (e.g., sampling noise terms).

Table 3: Time costs of PS-NTRUReEncrypt

<table>
<thead>
<tr>

<td>( t_m + t_s )</td>
</tr>
<tr>
<td>Decryption</td>
<td>–</td>
<td>–</td>
</tr>
</tbody>
</table>

With regard to the theoretical space costs, this scheme shares the same results as NTRUReEncrypt, presented in Table 1. However, when considering an experimental instantiation, the parameters used would not be the same, which implies that the experimental costs vary. In addition, given that we lack of a formal analysis for quantifying the level of security that is provided by the scheme, it is not possible to make a direct comparison. An experimental analysis of the costs of PS-NTRUReEncrypt is presented in Section 5.3.

5. SOME EXPERIMENTAL RESULTS

In order to validate the viability of the proposed proxy re-encryption schemes, we have developed and tested an implementation of our proposals. Since we propose two schemes, we have two different implementations. NTRUReEncrypt is implemented on top of an available open-source Java implementation of NTRU [1]. For PS-NTRUReEncrypt, due to its non-standard nature, we had to code it from scratch; however, we made use of the functionalities provided by the Java Lattice-Based Cryptography (jLBC) library [14]. Our execution environment consists on an Intel Core 2 Duo @ 2.66 GHz. Although this processor has two cores, our implementation only uses one of them, as it is not parallel.

5.1 Performance of NTRUReEncrypt

The first experiment consisted of measuring the performance of the first proposed scheme using different set of parameters. We have used the parameter sets proposed in [28], although other parameters could be studied. Besides the basic implementation, we have made also some optimizations, such as the possibility of using product-form polynomials [28], which has a great effect on performance.

In Table 4, we give the execution times for the encryption, decryption and re-encryption for each parameter set. Parameters are represented by a tuple \((n, \text{prod}, k)\), where \text{prod} is a boolean parameter that indicates the use of product-form polynomials, and \(k\) is the claimed security level (in bits). Additional parameters are fixed, such as \( q = 2048 \) and \( p = 3 \).

For each set of parameters, the experiment consisted of a looped execution, where a random message from the plaintext space is sequentially encrypted, re-encrypted and decrypted, and new keys are used on each iteration. The time for each operation is computed as the average of 100 iterations. Since sampling random elements is an operation that can be performed off-line, we decided to exclude it from the time measurements; thus, times reflected in this experiment only reflect the operations that must be performed on-line. This approach was also followed by [19].

<td>0.32</td>
<td>1.67</td>
<td>1.66</td>
<td>42</td>
</tr>
</tbody>
</table>

For example, the sixth set of parameters was already used for a previous NTRU benchmark [19], and we can see that our results are consistent with their study, where they obtained a measure of approximately 0.31 ms for encryption (3220 encryptions per second).

In addition, Table 4 also shows the average number of re-encryptions supported by each parameter set. As stated in Section 3.2.2, the inclusion of the error term \( pe \) during the re-encryption process produces an increasing error that grows on each hop, causing a decryption failure at some point. It can be seen that this depends on the choice of parameters, so increasing the parameters actually decreases the probability of decryption failure.

5.2 Comparison of NTRUReEncrypt with other proxy re-encryption schemes

In order to benchmark our proposal with respect to other proxy re-encryption schemes, we have implemented three schemes. Two of them share similar properties than ours (i.e., bidirectional and multihop). One of them is the BBS scheme [11], which is CPA-secure as ours, while the other is the one proposed by Weng et al [27], which is proven CCA-secure; note, however, that the latter scheme achieves a better notion of security than ours, and hence, the comparison is unbalanced in this case. Both of them are implemented in Java using elliptic curve cryptography over a prime field. Specifically, we used the NIST P-256 curve, which provides 128 bits of security [10]. In addition, and for the sake of comparison, we have also implemented a third scheme from Aono et al [4]; note that in this case, this scheme is not bidirectional. For our scheme, we have used the \text{csl171cep1} parameter set from [28], which achieves 256 bits of security. This parameter set corresponds to the sixth row of Table 4. We chose this parameter set because it was already used for a previous NTRU benchmark [19]. With regard to the experimental setting, we have used the same environment as before.
Figure 1: Comparison with other proxy re-encryption schemes

Figure 1 shows the results of our experiment. It can be seen that our scheme outperforms the others, as it is between 10 and 20 times faster. The scheme from Aono et al shows a similar performance in encryption and decryption, but is 20 times slower for re-encryption. The results obtained for our scheme are consistent with previous benchmarks for NTRU [19], as we used the same parameters.

For our experiment, we also implemented other unidirectional schemes, specifically, the ones from Ateniese et al [7] and Libert and Vergnaud [21]. However, we exclude them from this comparison since they are much slower due to the use of bilinear pairings; Appendix B presents these omitted results.

5.3 Performance of PS-NTRUReEncrypt

Table 5 shows the computation time of the main operations of PS-NTRUReEncrypt. It can be seen that the computation time for the main operations is approximately the same for each parameter set. This is also shown in Figure 2. Note that this figure is in logarithm scale, so the growth in computation time is exponential as \( n \) increases. This is a consequence of requiring that \( n \) is a power of 2, which restricts the choice of parameters.

Table 5: Computation time (in ms) of PS-NTRUReEncrypt for different parameters

<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>( n = 32, \log_2 q = 23 )</td>
<td>0.93</td>
<td>0.99</td>
<td>1.05</td>
</tr>
<tr>
<td>( n = 64, \log_2 q = 28 )</td>
<td>4.53</td>
<td>4.23</td>
<td>4.32</td>
</tr>
<tr>
<td>( n = 128, \log_2 q = 32 )</td>
<td>17.28</td>
<td>17.32</td>
<td>17.45</td>
</tr>
<tr>
<td>( n = 256, \log_2 q = 37 )</td>
<td>80.64</td>
<td>81.045</td>
<td>86.56</td>
</tr>
<tr>
<td>( n = 512, \log_2 q = 41 )</td>
<td>333.75</td>
<td>334.07</td>
<td>359.54</td>
</tr>
<tr>
<td>( n = 1024, \log_2 q = 46 )</td>
<td>1333.03</td>
<td>1344.10</td>
<td>1461.46</td>
</tr>
</tbody>
</table>

Unlike the first scheme, we do not provide a comparison of PS-NTRUReEncrypt to other proxy re-encryption schemes. We cannot directly compare it to other schemes without properly analyzing the security level it achieves, which is done indirectly through evaluating the security against the best known lattice attacks [26].

With regard to the number of hops of this scheme, the results now are much better than in NTRUReEncrypt, where we had just up to 50 re-encryptions, with the parameter sets used. In this case, we were unable to find a maximum number of hops, having executed more than 10000 re-encryptions for each parameter set, without finding any decryption failure. This lead us to think that the parameters used in PS-NTRUReEncrypt are actually very conservative, which explains also that its performance is lower than NTRUReEncrypt. These parameters are, however, derived from the theoretic assumptions; it is an open problem to find ways to decrease them.

Other factor that could impact the results is that the implementation is not as optimized as NTRUReEncrypt, since we had to code it from scratch. In order to improve our implementation, we can make use of optimizations such as faster algorithms for polynomial multiplication, based on the Fast Fourier Transform (FFT).

Table 6: Space costs (in KB) of PS-NTRUReEncrypt for different parameters

<table>
<thead>
<tr>
<th>Parameters</th>
<th>Size of polynomials</th>
</tr>
</thead>
<tbody>
<tr>
<td>( n = 32, \log_2 q = 23 )</td>
<td>0.09</td>
</tr>
<tr>
<td>( n = 64, \log_2 q = 28 )</td>
<td>0.22</td>
</tr>
<tr>
<td>( n = 128, \log_2 q = 32 )</td>
<td>0.50</td>
</tr>
<tr>
<td>( n = 256, \log_2 q = 37 )</td>
<td>1.16</td>
</tr>
<tr>
<td>( n = 512, \log_2 q = 41 )</td>
<td>2.56</td>
</tr>
<tr>
<td>( n = 1024, \log_2 q = 46 )</td>
<td>5.75</td>
</tr>
</tbody>
</table>

As for the space costs, Table 6 shows the size in KB of the polynomials produced by different parameters. Recall that in our schemes, all the elements of the cryptosystem (i.e., public and secret keys, re-encryption keys, and ciphertexts) are represented by the same kind of polynomials.
6. CONCLUSIONS

In this paper we describe NTRUReEncrypt, a highly-efficient proxy re-encryption scheme based on the NTRU cryptosystem. This scheme is bidirectional and multipath, but not collusion-resistant. The key strength of this scheme is its performance. Experimental results show that this scheme outperforms previous proposals by an order of magnitude, and there is room for even more improvement, for instance using parallelization techniques, as shown in [19]. We believe that the level of efficiency shown by NTRUReEncrypt opens up new practical applications of proxy re-encryption in constrained environments. In addition to this scheme, we propose PS-NTRUReEncrypt, a provably-secure variant that is CPA-secure under the hardness of lattice problems, namely the Ring-LWE problem.

With regard to future work, there are several areas with potential for improvement. The most pressing are achieving CCA-security and the definition of a unidirectional and collision-resistant scheme. Another subject is improving the parameters of NTRUReEncrypt, since this could decrease the probability of decryption failures after multiple re-encryptions. Additionally, it would be interesting to come up with better bounds for the provably-secure version and an analysis of the selection of parameters based on the best known attacks. Finally, we want also to extend the experimental analysis to other lattice-based proxy re-encryption schemes.

8. REFERENCES

APPENDIX

A. SECONDARY LEMMAS

In this section we present two secondary lemmas, both presented in [26]. The first lemma provides bounds for the secret keys generated using the key generation algorithm:

Lemma 1. [26, Lemma 3.6] Let \( n \) be a power of 2, \( q \) a prime so that \( q = 1 \mod 2n \), and \( \deg(p) \leq 1 \). Let \( \sigma \geq \sqrt{n \log n} \cdot q^{1/n} \). The secret key polynomials \( f \) and \( g \) returned by the KeyGen algorithm satisfy \( \|f\| \leq 4\sqrt{n||p||\sigma} \) and \( \|g\| \leq \sqrt{n\sigma} \), with probability \( \geq 1 - 2^{-n^{2/3}} \).

The second lemma provides bounds to the product of arbitrary polynomials of \( \mathcal{R} \) with samples from a distribution from \( \Psi_n \):

Lemma 2. [26, Lemma 2.10] Let \( y, r \in \mathcal{R} \), with \( r \) fixed and \( y \) sampled from a distribution from \( \Psi_n \), with \( aq \geq n^{0.25} \). Then: \( \Pr \left[ \|y\|_\infty \geq aq^{-0.25} \omega(\log n) \cdot \|r\| \right] \leq n^{-\omega(1)} \).

B. PERFORMANCE EVALUATION OF PROXY RE-ENCRYPTION SCHEMES

In addition to the schemes shown in the experimental comparison, we also implemented two more schemes from Ateniese et al [7] and Libert and Vergnaud [21], both of them unidirectional and the latter secure against chosen ciphertext attacks. However, being based on pairings, these schemes have proven to be much slower, so we drop them from our main analysis. Since we are unaware of any previous work that benchmarks actual implementations of proxy re-encryption schemes, we decided to include this evaluation as an appendix.

We implemented these additional schemes using the jPBC library [15], a pairing-based cryptography library for Java. As for the cryptographic details, we used a supersingular curve of the form \( y^2 = x^3 + x \), with a 256-bit group order and 3072 bits for the field size, which achieves 128 bits of security [16][9]. Additionally, we have made extensive use of exponentiation and pairing preprocessing of frequently-used elements for efficiency reasons. This is a very useful functionality of jPBC that allows the preprocessing of exponentiation operations for efficiency reasons, since there are several elements that are frequently exponentiated, such as the generators of the groups and the public keys.

Table 7 shows the results obtained from our experiments, including the schemes from Ateniese et. al and from Libert and Vergnaud. For the particular case of re-encryption, which is the most common operation for most applications of proxy re-encryption, it can be seen that NTRUREncrypt outperforms the others. Note also that the security level for the proxy re-encryption schemes is 128 bits, while the provided by NTRUREncrypt with the used parameters is 256 bits; if we increase the parameters in the rest of the schemes in order to achieve 256 bits of security, then these times would be much higher.
